Field of Invention

10 The present invention relates to single nucleotide polymorphisms in
nucleic acids involved in encoding enzymes in the testosterone biosynthetic
pathway and to methods for detecting such polymorphisms. The invention has
utility in the diagnosis, prognosis, prevention and treatment of disease,
particularly those relating to prostate cancer and breast cancer.

15

Background of the Invention

Prostate cancer is the most common non-skin cancer in males all over the
world. Currently, there are no means to predict how aggressive an individual's
cancer will be. Thus, many patients are given unnecessary drastic treatment with
20 severe side effects and possibly others do not receive treatment effective
enough.

Incidence of prostate cancer shows strong age dependence, being a
disease of old men, and strong race dependence, being almost twice as common
in African Americans as in Caucasians, while Asian populations have the lowest
25 risk (Cook et al. (1999) J Urol 161, 152-155; Hsing et al. (2000) Int J Cancer 85,
60-67). The third well-known risk factor is having a family history of prostate
cancer (Cerhan et al. (1999) Cancer Epidemiol Biomarkers Prev 8, 53-60; Kalish
et al. (2000) Urology 56, 803-806), and several studies have supported the
presence of predisposing genetic factors.

30 Genome wide linkage analyses have pointed multiple chromosomal
regions showing linkage in prostate cancer families and several prostate cancer
candidate loci have been suggested; HPC1 in 1q24 (Smith et al. (1996) Science
274, 1371-1374), HPCX in Xq27 (Xu et al. (1998) Nat Genet 20, 175-179), PCAP

in 1q42.2 (Berthon et al. (1998) Am J Hum Genet 62, 1416-1424), CABP in 1p36 (Gibbs et al. (1999) Am J Hum Gen 64, 776-787), and *HPC2/ELAC2* in 17p (Tavtigian et al. (2001) Nat Genet 27, 172-180). Recently, a candidate cancer-susceptibility gene, *RNASEL*, was cloned at the HPC1 loci (Carpten et al. (2002) Nat Genet 30, 181-184) and two possibly deleterious germline mutations segregating in prostate cancer families were discovered.

The growth of prostate cells is dependent on active testosterone (Ekman (1995) J Urol 101, 22-25) and strikingly, prostate adenocarcinomas can be created by testosterone administration in rats (Gupta et al. (1999) Cancer Res 59, 2115-2120). Testosterone seems to be a strong tumour promoter for the rat prostate, even at doses that do not measurably increase circulating testosterone (Bosland et al. (1991) Princess Takamatsu Symp 22, 109-123). Consequently, genes involved in the testosterone biosynthetic pathway, e.g., *CYP17*, *CYP3A4*, and *SRD5A2* (Figure 1) are good candidates for being involved in the initiation and progression of prostate cancer. Several polymorphisms have been discovered in these genes and some of them show association either with increased risk or progression of prostate cancer (Table 1). Nevertheless, there is no evidence of higher testosterone levels in prostate cancer patients.

Approximately 55 different Cytochrome P450 genes are present in the human genome and are classified into different families and subfamilies on the basis of sequence homology. Members of the CYP3A subfamily catalyze the oxidative, peroxidative and reductive metabolism of different endobiotics, drugs, and protoxic or procarcinogenic molecules. As an example, CYP3A4 is responsible for the oxidative metabolism of an estimated 60% of all clinically used drugs. Up to 30-fold interindividual differences in expression has been detected, causing variation in oral bioavailability and systemic clearance of CYP3A substrates, such as HIV protease inhibitors, several calcium channel blockers and some cholesterol-lowering drugs. Variation in CYP3A expression is particularly important in substrates with narrow therapeutic indices, such as cancer chemotherapeutics and immunosuppressants. Variation in CYP3A expression can result in clinically significant differences in drug toxicities and response.

As with prostate cancer, breast cancer also shows age-dependency indicating a possible hormonal influence on the disease risk. Endogenous oestradiol synthesis takes place in the ovarian theca cells of pre-menopausal women, in the stromal adipose cells of the breast of post-menopausal women, and in minor quantities in peripheral tissue. These cells, as well as breast cancer tissue, express all the necessary enzymes for this synthesis, including *CYP17*, and enzymes that further hydroxylate oestradiol, such as *CYP3A4* (Kristensen et al. (2000) *Mutat Res* 462, 323-333). Thus, polymorphisms in these enzymes may also be associated with the risk of breast cancer (Kristensen et al. (2000) *Mutat Res* 462, 323-333). Furthermore, *CYP3A4* is also involved in the activation of many mammary carcinogens, such as the polycyclic aromatic hydrocarbons and heterocyclic amines (Guengerich et al. (1991) *Chem Res Toxicol.* 4, 168-179). According to a recent study (Zheng et al. (2001) *Cancer Epidemiol Biomarkers Prev* 10, 237-242), high *CYP3A4* activity may be a risk factor for breast cancer risk.

Single nucleotide polymorphisms (SNPs) are the most common type of genetic variation in the human genome, and are expected to be helpful in identifying human disease genes. In addition to occurring frequently, on average every 500-2,000 bp (Li & Sadler (1991) *Genetics* 129, 513-523; Chakravarti (1998) *Nat Genet* 19, 216-217; Cargill et al. (1999) *Nat Genet* 22, 231-238; Halushka et al. (1999) *Nat Genet* 22, 239-247), SNPs have a low mutation rate when compared to microsatellite markers, both of which are characteristics that may have particular advantages for association analysis. The utility of SNPs is not only in their use as markers for discovering additional functional variants and for the general evaluation of a specific gene in the context of a given clinical phenotype but also in their potential functional relevance. However, rather than finding a single SNP with drastic effect on the phenotype, more likely it will be multiple SNPs in relevant genes, either linked (i.e., grouped as a haplotype) or independent (perhaps on different chromosomes), that contribute to the phenotype.

Recently, several studies have shown the utility of haplotypes, i.e., a combination of SNPs with alleles physically assigned to a chromosome, in association analysis (Daly et al. (2001) *Nat Genet* 29, 229-232). Studying

haplotypes might give the analysis more power but traditionally demands either samples from multiple generations or tedious molecular haplotyping.

Alternatively, several algorithms have been developed for inferring haplotypes from genotype data (Clark (1990) Mol Biol Evol 7, 111-122; Excoffier & Slatkin
5 (1995) Mol Biol Evol 12, 921-927; Stephens et al. (2001) Am J Hum Genet 68, 978-989). These algorithms have been proven to work with a very low error rate (Drysdales et al. (2000) PNAS 97, 10483-10488). In a sense, haplotyping is equivalent to performing a study in a family or other select group of people. It helps to get back the power of linkage, and can be regarded as a crucial step in
10 association studies using random individuals.

WO02/055735 discloses specific nucleic acids useful for identifying, diagnosing, monitoring, staging, imaging and treating prostate cancer and breast cancer. Similar compositions comprising prostate specific nucleic acids are described by the same applicant (Diadexus Inc.) in related applications
15 (WO02/42776, WO02/42499, WO02/42463, WO02/42329, WO02/39431, WO02/239431, WO02/38810, WO02/38810, WO02/236808 and WO0224718).

Diadexus Inc. have also disclosed a method of diagnosing, monitoring, staging, imaging and treating prostate and breast cancer by means of specific nucleic acids, in a series of related applications (WO01/39798 & WO00/23111 &
20 WO00/23108).

WO01/53537 (DZ Genes Inc.) describes isolated polynucleotides containing at least one polymorphism useful for the diagnosis of disease, particularly prostate and breast cancer.

Single nucleotide polymorphisms associated with prostate cancer are
25 disclosed in WO01/83828, as are methods for using these SNPs to determine susceptibility to this disease.

In order to improve the lives of prostate and breast cancer patients it is essential to develop prognostic markers for cancer as well as markers allowing general assessment of disease risk. Patients need to be categorized into those
30 needing immediate, extensive treatment, and those who just need watchful waiting. As a result, prostate and breast cancer mortality could be reduced and unnecessary side effects caused by invasive treatments could be avoided. There is therefore a need for prognostic molecular markers for aggressive breast and

prostate cancer to aid predicting, diagnosing and monitoring these diseases in individuals. Furthermore, there is a continued need for improved methods of treatment of both conditions in patients. The present invention addresses these needs and provides improvements over the prior art in the form of novel and
5 specific nucleic acids, microarrays and kits useful for the diagnosis of breast and prostate cancer.

In a seventh aspect of the present invention, there is provided a method of treatment or prophylaxis of a subject comprising the steps of

- i) analysing a biological sample containing nucleic acid obtained from the subject to detect the presence or absence of at least one single

- nucleotide polymorphism in SEQ ID NOS 1-36 or SEQ ID NOS 42-45, or the complement thereof, associated with a disease, condition or disorder related to prostate or breast cancer; and
- ii) treating the subject for the disease, condition or disorder if step i) detects the presence of at least one single nucleotide polymorphism in SEQ ID NOS: 1-36 or SEQ ID NOS 42-45, or the complement thereof.

Treatment may take a variety of forms depending upon the nature of the cancer. Hormonal therapy is a widely used treatment for patients with metastatic carcinoma of the prostate (Goethuys et al. (1997) Am J Clin Oncol. 20, 40-45). Such treatment may, for example, involve androgen deprivation by surgical (e.g. orchiectomy) or androgen suppressive agents such as estrogens, (e.g. diethylstilbestrol), antiandrogens (e.g. flutamide) and luteinising hormone-releasing hormone agonists (e.g. leuprolide). Radiotherapy using radionuclides, such as ³²Phosphorus or ⁸⁹Strontium, can be an effective treatment for the disease. There is also growing interest in the development of vaccines (Slovin (2001) Hematol. Oncol. Clinic N. Am, 15, 477-496) or the use of gene therapeutic methods (Ferrer & Rodriguez (2001) Hematol Oncol Clinic of N. Am 15, 497-508) for the treatment of prostate cancer.

Suitably, the nucleic acid is selected from the group consisting of DNA, RNA and mRNA.

Preferably, the sample is analysed to detect the presence or absence of at least one single nucleotide polymorphism at a position selected from the group consisting of position [CYP3A4_IVS9 +187] of SEQ ID No. 1, position [CYP3A4, 1639 base pairs after the stop codon] of SEQ ID No. 2, position [CYP3A4, 945 base pairs after the stop codon] of SEQ ID No. 3, position [CYP3A4_5' region -747] of SEQ ID No. 4, position [CYP3A4_IVS7 -202] of SEQ ID No. 5, position [CYP3A4, 2204 base pairs after the stop codon] of SEQ ID No. 6, position [CYP3A4_IVS2 -132] of SEQ ID No. 7, position [CYP3A4_IVS1 -868] of SEQ ID No. 8, position [CYP3A4_5' region -847] of SEQ ID No. 9, position [CYP3A4, 766 base pairs after the stop codon] of SEQ ID No. 10, position [CYP3A4, 1454 base pairs after the stop codon] of SEQ ID No. 11, position [CYP3A4_IVS3 +1992] of SEQ ID No. 12, position [CYP3A4_IVS9 +841] of SEQ ID No. 13, position

Detailed Description of the Invention

Approach

- A two-phase study was undertaken of CYP17, CYP3A4, and SRD5A2, to evaluate the relationship between their genotypes/haplotypes and prostate cancer. Phase I of the study first searched for single nucleotide polymorphisms
- 20 (SNPs) in these genes by re-sequencing 24 individuals from Coriell Polymorphism Discovery Resource (Coriell Cell Repositories, Camden, NJ), approximately 100 men from prostate cancer case-control sibships, and by leveraging public databases. Eighty-seven SNPs were discovered and genotyped in 276 men from case-control sibships. Those SNPs exhibiting preliminary case-
- 25 control allele frequency differences, or distinguishing (i.e., 'tagging') common haplotypes across the genes, were identified for further study (24 SNPs total). In Phase II of the study, the 24 SNPs were genotyped in an additional 841 men from case-control sibships. Finally, associations between genotypes/haplotypes in CYP17, CYP3A4, and SRD5A2 and prostate cancer were evaluated in the total
- 30 case-control sample of 1,117 brothers.

Subjects

A family-based association study population of 1,117 men (637 cases, 480 controls) was recruited between January 1998 and January 2001 from the major medical institutions in the greater Cleveland area and from the Henry Ford Health System in Detroit. The study was approved by the collaborating institution's Review Boards, and informed consent was obtained from all participating men. Characteristics of the study population have been described (Casey et al. (2002) Nat Genet 32, 581-583).

Men diagnosed with histologically confirmed prostate cancer at age 73 or younger were invited to join the study if they had a living unaffected brother who was either older than the proband, or at most eight years younger than the age at diagnosis of the proband. This age restriction was selected in an attempt to increase the potential for genetic factors affecting disease, and to help make certain that the controls were not unaffected due simply to being of a younger age. To help confirm that the controls were not diseased, the prostate specific antigen (PSA) levels in their blood was tested. Individuals in the study with PSA levels above 4 ng/ml were retained as 'controls' unless a subsequent diagnosis of prostate cancer was made, at which time they were reclassified as cases. Keeping them in the study was important because automatically excluding men with elevated PSA levels regardless of their ultimate prostate cancer status can lead to biased estimates of association (Lubin & Hartge (1984) Am J Epidemiol 120, 791-793; Poole (1999) Am J Epidemiol 150, 547-551). Information on the cases' Gleason score (a measure of prostate cancer cellular differentiation) and tumor stage (TNM, tumor-node-metastasis stage) was determined from their medical records. The study population was comprised of 90% Caucasians (European Americans), and the remainder primarily African American (9%).

Polymorphism discovery

Polymorphisms were discovered by sequencing individuals from prostate cancer sibships (67 cases and 43 controls for CYP17 and CYP3A4, and 51 cases and 41 controls for SRD5A2). Of the 110 individuals sequenced for CYP17 and CYP3A4, 106 were Caucasian, 2 were Hispanic, and 2 were African-American. Of the 92 individuals sequenced for SRD5A2, 84 were Caucasian and 8 were

African American. In addition, the 24 individuals from the Coriell Cell Repository Polymorphism Discovery Resource (Collins et al. (1998) Genome Res 8, 1229-1231) were sequenced against the three genes.

PCR primers covering coding regions, splice sites, 5' and 3' regions, and parts of introns of *CYP3A4* (reference sequence No. 39), *CYP17* (reference sequence No. 40), and *SRD5A2* (reference sequence No. 41), were designed using the Primer3 program (<http://www.genome.wi.mit.edu/cgi-bin/primer/primer3.cgi>). PCR products were sequenced using energy transfer dye terminators on the Amersham Bioscience's MegaBACE1000 (Amersham Biosciences, Sunnyvale, California) using standard protocols. Sequence analysis was performed by assigning quality values (Phred; University of Washington, Seattle, Washington), assembling contigs (Phrap; University of Washington), automated identification of candidate heterozygote SNPs (PolyPhred, University of Washington), automated identification of candidate homozygote SNPs (High Quality Mismatch, Amersham Biosciences, Sunnyvale, California) and by operator confirmation (Consed, University of Washington). All polymorphisms were confirmed by Single Nucleotide Primer Extension (SNuPE) assay (Amersham Biosciences, Sunnyvale, California)

In addition to novel polymorphisms discovered in this study, several publicly available SNPs from the dbSNP (<http://www.ncbi.nlm.nih.gov/SNP/>), Utah Genome Center (UGC) (<http://www.genome.utah.edu/genesnps/genes/>), the Human Cytochrome P450 Allele Nomenclature Committee (HCANC) (<http://www.imm.ki.se/CYPalleles/>), the Human Gene Mutation Database (HGMD) (<http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html>) and the Human Genic Bi-Allelic SEquences (HGBASE) Release 8 (<http://hgbase.interactiva.de/>) were searched for *CYP17*, *CYP3A4*, and *SRD5A2*. For the *Androgen Receptor* gene, several publicly available SNPs from dbSNP, HGBASE and the Androgen Receptor Mutation Database (ARMD) (<http://ww2.mcgill.ca/androgendb/>) were included.

Genotyping

In Phase I, 276 individuals from prostate cancer sibships were genotyped for 29 SNPs (11 novel, 18 known) in *CYP17*, 33 SNPs (18 novel, 15 known) in

CYP3A4, and 25 SNPs (5 novel, 20 known) in *SRD5A2*. The individuals included 153 cases and 123 brother controls, 70% European Americans and 30% African Americans. The information from the 276 men was then used to determine initial case-control frequency differences and haplotype tagging. The results were then
5 used to determine which SNPs should be genotyped in the remainder of the study population (i.e. in Phase II of the study).

In Phase II, a total of 24 SNPs were genotyped in 841 individuals, giving information on a total of 1117 individuals for Phase II.

Genotyping was performed utilizing the Single Nucleotide Primer
10 Extension (SNUPE) assay on the MegaBACE1000 (Amersham Biosciences, Sunnyvale California) capillary electrophoresis platform (Amersham Biosciences). The Primer3 program (<http://www.genome.wi.mit.edu/cgi-bin/primer/primer3.cgi>) was used to design PCR primers to amplify regions containing the SNPs of interest. PCR fragments were purified with 0.5U of Shrimp Alkaline Phosphatase
15 (Amersham Biosciences) and 10U of Exonuclease I (Amersham Biosciences) by incubating at 37°C for 40 min and at 85°C for 15 min. The single base extension (SBE) reaction was set with 1 pmol of HPLC purified SBE primer, 2-4 µl of SNUPE Premix (Amersham Biosciences), 2-4 µl of sterile water, and 1 µl of purified PCR fragment, and incubated at 25 cycles of 96°C for 10 sec, 50°C for 5
20 sec, and 60°C for 10 sec. For phase I of the study, SNUPE reactions were set in 96-well plates at 10 µl volume and purified with AutoSeq™96 Plates (Amersham Biosciences) prior to injecting into the MegaBACE1000 system. For phase II of the study, SNUPE reactions were set in 384-well plates at 5-6 µl volume, diluted with 3-4 µl of sterile water and purified with 1 U of Shrimp Alkaline Phosphatase
25 (Amersham Biosciences) by incubating at 37°C for 45 min and at 85°C for 15 min prior to injecting into the MegaBACE4000 system. In cases where low signal was anticipated (due to faint PCR), SNUPE reactions were desalted using a custom 384-well filter plate incorporating modified size-exclusion technology (Millipore Corporation, Billerica, MA). The Scierra Genotyping LWS™ (Amersham
30 Biosciences) system was utilized for the tracking and management of samples and laboratory activity for Phase II of the study.

Specific software (SNPriDe) was developed for the automated design of SNUPE primers. Using a purified PCR fragment containing the SNP of interest as

a template, a third, internal primer was designed so that the 3' end anneals adjacent to the polymorphic base-pair, and during the SNUPE reaction a fluorescently labeled dideoxynucleotide (terminator) was added onto the primer. A separate software package has been developed (SNP Profiler™, Amersham Biosciences) that automatically processes the signal data and outputs the maximum likelihood SNP genotypes. The system includes a user interface for editing and verification.

Three SNPs, SRD5A2_SNP20 (V89L), SRD5A2_SNP22 (A49T) and CYP17_SNP29(-34>C) were analysed by restriction enzyme digestion (Cicek et al., unpublished data).

Proofreading genotype data

A large number of haplotypes inferred during initial rounds of haplotyping implied erroneous genotype data. A phylogenetic study of inferred haplotypes was performed to reveal the relationships between different haplotypes. All haplotypes differing from another haplotype by only one SNP, and being represented by only one individual, were subject to inspection. Genotype data for the individual at stake were reanalysed by SNP Profiler™ (Amersham Biosciences) to exclude the possibility of an incorrect genotype. Rounds of phylogenetic study of haplotypes, followed by reanalysing suspicious genotypes and inferring new haplotypes were applied until no more incorrect genotypes could be found. Three to six rounds were applied for each of the genes.

Haplotyping

Alleles within each of the three candidate genes were in strong linkage disequilibrium with one another. Thus, for each gene, haplotypes were estimated using the resulting genotypes, by disease status and within major ethnic groups using the software PHASE. This program uses Markov chain Monte Carlo to estimate haplotypes, imputes information for missing genotypes, and incorporates a statistical model for the distribution of unresolved haplotypes based on coalescent theory (Stephens et al. (2001) Am J Hum Genet 68, 978-989).

Haplotypes and haplotype tagging SNPs were first determined among the 276 men genotyped for Phase I of the study, where tagging SNPs was necessary to define the most common haplotypes (e.g., >5%). After completing genotyping on the entire study population (Phase II of the study), the resulting data were used to estimate haplotypes.

Association analysis

Case versus control allele frequencies were first compared within major ethnic groups. Then the association between the resulting genotypes/haplotypes and prostate cancer risk was evaluated by calculating odds ratios (OR, estimates of relative risk) and 95% confidence intervals from conditional logistic regression with family as the matching variable, using a robust variance estimator that incorporates familial correlations. This is a standard approach for analyzing sibling matched case-control data, although sibling sets without any controls do not contribute any information (197 cases total here) (Breslow and Day (1980) IARC Sci Publ 32, 335-338). In the analyses of CYP17, CYP3A4, and SRD5A2 a log-additive coding was used which treats the most common polymorphism (or haplotype) as the null-risk referent group and assumes that the relative risk of carrying one polymorphism (or haplotype) is the square-root of the risk of carrying two. Since haplotypes were estimated for these three genes, the probabilities of observed haplotypes were used in the analyses (Schaid et al. (2002) Am J Hum Genet 70, 425-434).

To control for potential confounding, age was adjusted for in all regression models. In addition to looking at the main effects of each SNP or haplotype, the analyses were also stratified by the case's disease aggressiveness, where high aggressiveness was defined by TNM stage \geq T2B or Gleason score \geq 7; and low aggressiveness by TNM stage < T2B and Gleason score < 7. All statistical analyses were undertaken with the S+ software (version 6.0, Insightful Corp, 2001).

Polymorphism discovery (Phase I)

A total of 34 novel SNPs were detected: 11 in CYP17, 18 in CYP3A4, and 5 in SRD5A2 (Table 2). In addition, 11 SNPs were "rediscovered" from the public

databases. Including these 11 SNPs, 53 SNPs were selected in total from the databases: 18 in *CYP17*, 15 in *CYP3A4*, and 20 in *SRD5A2*. These were chosen based on the intention to obtain an even distribution of SNPs across the genes and the availability in the databases at that time (January-April 2001). Twenty-
5 one SNPs were chosen from dbSNP, 27 from GeneSNPs, 12 from HGMD, 8 from HGVbase, and 2 from HCAN (the total number of SNPs listed here exceeds 53 as several SNPs were present in multiple databases). Table 3 lists all 87 SNPs (34 novel, 53 from databases), with their origins, exact locations and allele frequencies.

10 Among the 34 novel SNPs, 26 (76%) were discovered in both the Coriell and case-control populations. Three SNPs were only observed in the Coriell data, and the remaining five were found only in the prostate cancer sibships. Of these five, three were relatively rare (allele frequencies 0.2-1.5%), suggesting that they may not have been discovered in the Coriell population simply due to its small
15 sample size (n=24). Nevertheless, the other two SNPs that were only found in the prostate cancer sibships (*CYP3A4*_SNP12 and *CYP17*_SNP42) showed higher allele frequencies (7.5% and 21.8%, respectively), suggesting that they might be specific to the prostate cancer case-control population.

20 **Genotyping and Haplotyping**

Phase I

The 87 SNPs were genotyped in a total of 276 males from prostate cancer sibships (29 in *CYP17*, 33 in *CYP3A4*, and 25 in *SRD5A2*). Eleven SNPs gave ambiguous genotyping results. This might have been due to unoptimized
25 genotyping reactions or primer self-priming due to secondary structures and unspecificity of PCR and/or SNUPe primers, especially within the Cytochrome P450 gene family. Of the remaining 76 SNPs, a similar percentage of those novel (41%, or 12/29) and known (38%, or 18/47) had allele frequencies $\geq 10\%$. However, 19/47 (40%) of the known SNPs were found to be monoallelic in the
30 276 men, suggesting that they are either extremely rare, population specific, or artifacts.

In light of these results, the 11 SNPs with ambiguous genotype results, the 19 SNPs that appeared monoallelic in all samples tested, and an additional four

that were seen only in the Coriell Diversity Set but not in the prostate cancer sibships were excluded. Also excluded was one SNP because >15% of data was missing (due to a low success rate for PCR and SNUPe reaction). Finally, 12 SNPs were excluded because their minor allele frequencies were less than 5% in all of the following four subgroups: European Americans, African Americans, cases, and controls (Table 3). Following these exclusions, a total of 40 SNPs remained for consideration in the Phase II association study (14 in *CYP17*, 16 in *CYP3A4*, and 10 in *SRD5A2*) (Table 3).

Using the preliminary genotype information, haplotypes estimated with a frequency $\geq 5\%$ in at least one of the four major subgroups (i.e., European American, African American, cases, or controls) were identified. Each gene had a single "common" haplotype, with a frequency ranging between 42 and 51 percent (not shown). Haplotype tagging SNPs were identified and used as a basis for inclusion in Phase II of the study. In addition, non-tagging SNPs exhibiting suggestive case versus control allele frequencies were considered (Table 3). Altogether 24 SNPs were selected for Phase II.

Phase II

The 24 tagging and suggestive SNPs were genotyped in an additional 841 men, giving information on a total of 1117 individuals for Phase II. Case versus control allele frequency differences by ethnic group are presented in Table 3. Haplotypes estimated with a frequency $\geq 3\%$ in at least one of the four major subgroups of the study population were identified. The major haplotypes for *CYP17*, *CYP3A4*, and *SRD5A2* along with their frequencies are presented in Figure 2.

Association analyses

In the association analyses, no associations between *CYP17* genotypes/haplotypes and prostate cancer were detected. When looking at *CYP3A4*, SNP1 was found to be associated with an approximately 50% reduction in risk (OR=0.53, 95% CI=0.29-0.99; p-value=0.05) (Table 4A). Furthermore, the haplotype analysis revealed an association with an approximately 55% decrease in prostate cancer risk and *CYP3A4_Hap4* (OR=0.46, 95% CI=0.21-1.02; p-

value=0.05) (Table 5A). Two SNPs in SRD5A2 were also found to be associated with an approximately 50% increase in prostate cancer risk: SRD5A2_SNP26 (OR=1.57, 95% CI=1.08-2.30; p-value=0.02), and SRD5A2_SNP20 (V89L) (OR=1.56, 95% CI=1.08-2.25; p-value=0.02) (Table 4A). These SNPs, however,
5 were in almost complete linkage disequilibrium.

When the study population was stratified by high and low aggressiveness of prostate cancer, several interesting associations emerged (see Table 4B and 5B). First, five SNPs in CYP3A4 showed statistically significant associations with low aggressiveness: CYP3A4_SNP11 (CYP3A4*1B) (OR=0.20, 95% CI=0.06-
10 0.67; p-value=0.009), CYP3A4_SNP47 (OR=0.19, 95% CI=0.06-0.62; p-value=0.006), CYP3A4_SNP1 (OR=0.21, 95% CI=0.05-0.86; p-value=0.03), CYP3A4_SNP25 (OR=6.54, 95% CI=0.99-43.10; p-value=0.05) and CYP3A4_SNP15 (OR=0.41, 95% CI=0.22-0.79; p-value=0.007). Second, an association was observed between CYP3A4_Hap4 and low aggressiveness
15 (OR=0.06, 95% CI=0.008-0.50; p-value=0.009) (Table 5B). Finally, an inverse association was observed between SRD5A2_Hap3 and high aggressiveness (OR=0.52, 95% CI=0.29-0.91; p-value=0.02) (Table 5B).

Table 6 provides annotation of *CYP3A4*, *CYP17* and *SRD5A2* genomic sequences.

* SNP was discovered in the Coriell Diversity Set and was not present in the 276 individuals from prostate cancer sibships (still obviously a real SNP since it's seen in the Diversity Set)

@ ambiguous genotyping results; SNP was excluded from all further analyses. However, most likely real SNPs

The numbering system for the location of SNPs is according to the common mutation nomenclature (den Dunnen and Antonarakis (2000) Human Mut 15, 7-12; <http://www.dmd.nl/mutnomen.html#DNA>).

^a Explanations: (*), SNP did not show up in our study population; (R), rediscovered; (+), we had sequence coverage but did not rediscover the SNP; (+ <), we had sequence coverage but did not rediscover the SNP, most likely due to the low minor allele frequency; (-), we did not have sequence coverage explaining why we did not rediscover the SNP; (CDS), novel SNP discovered originally in the Coriell Diversity Set; (CAP), novel SNP discovered originally in the prostate cancer sibships; (C+C), novel SNP discovered originally in both populations

^b Underlined bases indicate the allele for which frequencies are given

^c Excluded from haplotyping in Phase I and from consideration for Phase II based on (A) being monoallelic in the prostate cancer sibships, (B) yielding ambiguous genotyping results, (C) low success rate, (D) allele frequency <5%. Included in Phase II association analyses based on (1) being a haplotype tagging SNP, (2) case-control difference in Phase I, (3) previous publications supporting association, (4) SNP conveniently located within the same PCR fragment as another included SNP

^d I, allele frequencies based on 276 samples; II, allele frequencies based on 1117 samples

^e NA, data not available
